Abstract:
Control-theoretic approaches to Active Queue Management (AQM) are typically based on linearizations of fluid flow models around design conditions. These conditions depend on the Round Trip Time (RTT), and the AQM performance is known to degrade if RTT values during actual operation depart substantially from design values. To overcome this difficulty a self-scheduled LPV controller for AQM is considered in this paper, where the controller is modified in real-time based on RTT. Simulations show that the self-scheduled LPV controller has good performance for both constant and time-varying RTTs, and outperforms two other common control-theoretic approaches to AQM.

Keywords: AQM, congestion control, control theory, fluid model, LPV systems, self-scheduled controller

1 Introduction

Congestion is one of the most important problems faced in communications networks. Congestion occurs when a link or node is carrying so much data that its quality of service deteriorates. This results in queueing delay, packet loss or the blocking of new connections, leading to low throughput and eventually to congestion collapse. On the other hand, links carrying less data than a certain level are also not desired as this implies that the link capacities are being underutilized [1]. Modern networks try to avoid these situations using congestion control techniques, among which Active Queue Management (AQM) is of particular interest. AQM operates by dropping or ECN-marking packets before the queue is full, according to a probabilistic rule. Earlier AQM disciplines such as RED [2] and REM [3] required careful tuning of parameters in order to provide good performance, while modern AQM disciplines such as ARED [4] and Blue [5] are self-tuning. With the development of dynamical models such as the fluid flow model in [6], control theoretic approaches for AQM have gained interest, including PI/PID controllers [7, 8] and robust $\mathcal{H}_\infty$ controllers [9–11]. These are based on the linearization of the fluid model, which produces a transfer function from probability of package mark $p$ to queue length $q$. One difficulty is that the transfer function is valid only for a given Round Trip Time (RTT), and a new transfer function must be obtained for a different RTT. In [12] switching between multiple controllers designed for different RTTs is considered and it is seen that higher number of controllers results in improved performance. However, if the number of controllers is too high, the implementation becomes very difficult and complicated. In addition, since RTT takes values on an interval, designing a controller for each RTT value requires an infinite number of controllers. In this paper a self-scheduled control design for AQM is considered to overcome these difficulties. The controller is parameterized in RTT and achieves stability and small tracking error for both fixed RTT as well as time varying RTT within a prescribed range.
2 Mathematical Model of TCP/AQM

A dynamical model for TCP congestion control was developed in [6] using fluid flow approximation. The dynamical model represents a bottleneck with multiple TCP flows sharing the link. The congestion avoidance is modeled as AIMD (additive-increase multiplicative-decrease). The dynamical model consists of the following nonlinear time-delayed differential equations

\[
\dot{W}(t) = \frac{1}{\theta(t)} - \frac{W(t) W(t - \theta(t))}{2 \theta(t - \theta(t))} p(t - \theta(t)) \tag{1}
\]

\[
\dot{q}(t) = \frac{N(t)}{\theta(t)} W(t) - C(t) \quad \text{for } q(t) > 0 \tag{2}
\]

where \(W\) is the TCP window size, \(q\) is the queue length, \(N\) is the number of TCP flows, \(C\) is the link capacity, \(p\) is the probability of packet mark and \(\theta\) is the RTT. Let \(C\) and \(N\) be constants for simplicity. The nonlinear system (1)-(2) can be linearized around an operating point to generate a transfer function from \(p\) to \(q\). Let \(\delta p := p(t) - p_o\) and \(\delta q := q(t) - q_o\) where \(q_o\) and \(p_o\) are the values at the operating point. Then a transfer function from \(\delta p\) to \(\delta q\) can be obtained as [6]

\[
\frac{\delta Q(s)}{\delta P(s)} = \frac{(C^3 \theta^3 N) e^{-\theta s}}{2N^2 \theta^3 C s^2 + (2N^2 C \theta^2 + 4N^3 \theta) s + 4N^3} \tag{3}
\]

where \(\theta\) is regarded as a parameter. One then has a different transfer function for each value of the RTT in the range \([\theta_{\min}, \theta_{\max}]\), where \(\theta_{\min}\) and \(\theta_{\max}\) are the minimum and maximum values of RTT for the link.

3 Controller Design

The controller must achieve stability of the closed-loop system and the tracking of a desired queue length, under the presence of constant or time-varying RTT within the specified range.\(^1\) A parameter dependent dynamic controller of the following form will be sought

\[
\dot{\zeta} = A_K(\theta) \zeta + B_K(\theta) e
\]

\[
\delta p = C_K(\theta) \zeta + D_K(\theta) e \tag{4}
\]

where \(\zeta\) is the controller’s internal state and \(e := \delta q_d - \delta q\) is the error between the desired and the actual queue sizes. A systematic method for the selection of the controller matrices \(A_K, B_K, C_K\) and \(D_K\) in (4) was derived in [13]. For this purpose the system to be controlled, i.e. (3), must be transformed into affine-parameter dependent form. Approximating the time delay \(e^{-\theta s}\) in (3) with a second order Pade approximation

\[
e^{-\theta s} \approx \frac{12 - 6 \theta s + \theta^2 s^2}{12 + 6 \theta s + \theta^2 s^2} \tag{5}
\]

and transforming into state space form yields

\[
\dot{x} = A_P(\theta) x + B_P(\theta) \delta p \tag{6}
\]

\[
\delta q = C_P(\theta) x \tag{7}
\]

\(^1\)Under ideal operation, RTT will be small for small queue size. However no such assumption will be made here, since unexpected changes in link conditions (e.g. increased propagation delay) can create longer RTTs even at smaller queue lengths. Thus, the controller is expected to be prepared for any RTT at any queue size (within the limits allowed).
where

\[ A_P(\theta) = \begin{bmatrix}
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 \\
-a_3 & -a_2 & -a_1 & -a_0
\end{bmatrix}, \quad (8) \]

\[ B_P(\theta) = \begin{bmatrix} 0 & 0 & 0 & 1 \end{bmatrix}^T, \quad (9) \]

\[ C_P(\theta) = \begin{bmatrix} b_2 & b_1 & b_0 & 0 \end{bmatrix} \quad (10) \]

and

\[ a_0 = 7\theta^{-1} + \frac{2N\theta^{-2}}{C}, \quad a_1 = \frac{14N\theta^{-3} + 18\theta^{-2}}{C}, \]

\[ a_2 = 12\theta^{-3} + \frac{36N\theta^{-4}}{C}, \quad a_3 = \frac{24N\theta^{-5}}{C}, \]

\[ b_0 = \frac{c^2}{2N}, \quad b_1 = -\frac{3c^2\theta^{-1}}{N}, \quad b_2 = \frac{6c^2}{N} \theta^{-2}. \]

Letting \( \Theta := \theta^{-1} \), and performing a series expansion around point \( \Theta = \Theta_o \), one can write \( A_P, B_P, C_P \) in terms of \( \Theta \) as

\[ A_P(\Theta) = A_{P0} + A_{P1}\Theta + \mathcal{O}(\Theta^2) \quad (11) \]

\[ B_P(\Theta) = B_{P0} + B_{P1}\Theta + \mathcal{O}(\Theta^2) \quad (12) \]

\[ C_P(\Theta) = C_{P0} + C_{P1}\Theta + \mathcal{O}(\Theta^2) \quad (13) \]

where \( A_{P0} \) has the same structure as in (8) but with

\[ a_0 = -\frac{2N\Theta_o^2}{C}, \quad a_1 = -\frac{28N\Theta_o^3}{C} - 18\Theta_o^2, \]

\[ a_2 = -\frac{108N\Theta_o^4}{C} - 24\Theta_o^3, \quad a_3 = \frac{-96N\Theta_o^5}{C}. \]

\( A_{P1} \) has the same structure as in (8) but with

\[ a_0 = \frac{4N\Theta_o}{C} + 7, \quad a_1 = \frac{12N\Theta_o^2}{C} + 36\Theta_o, \]

\[ a_2 = \frac{144N\Theta_o^3}{C} + 36\Theta_o^2, \quad a_3 = \frac{120N\Theta_o^4}{C}, \]

\( B_{P0} \) is equal to \( B_P \) in (9), \( B_{P1} \) is zero, \( C_{P0} \) has the same structure as in (10) but with

\[ b_0 = \frac{c^2}{2N}, \quad b_1 = 0, \quad b_2 = -\frac{6c^2\Theta_o^2}{N} \]

and \( C_{P1} \) has the same structure as in (10) but with

\[ b_0 = 0, \quad b_1 = -\frac{3c^2}{N}, \quad b_2 = \frac{12c^2\Theta_o}{N}. \]

Approximating \( A_P, B_P \) and \( C_P \) with the constant and linear terms in (11)-(13) produces an affine parameter dependent state space system (in \( \Theta \)) as desired. Self-scheduled controller design methods [13] can then be used to design the parameter dependent controller in (4) to meet the desired control objectives. The performance objective is to have a fast and well-damped response over the entire range of parameter values for step-like references. The control law is also required to achieve robustness by avoiding high-gain feedback at high-frequencies. This will prevent the excitation of high frequency modes and nonlinearities that were unmodeled or neglected.

Consider the feedback control structure depicted in Figure 1. The control problem described
above can be formulated as the minimization of the $\mathcal{L}_2$-induced norm of the operator mapping the signal $\delta q_d$ to signals $e$ and $\delta p$. The former map is the called the sensitivity function and denoted by $S$, and the latter map is denoted by $KS$. Following standard $\mathcal{H}_\infty$ design procedure, the performance objective and robustness objectives are specified through weighting filters $W_1(s)$ and $W_2(s)$, where $W_1(s) = 1/s$ for good tracking of step-like references, and $W_2(s)$ is a third order high pass Butterworth filter. This yields to an $\mathcal{H}_\infty$ optimization problem where the goal is to find a stabilizing controller $K$ for which the inequality

\[
\left\| \begin{bmatrix} \frac{W_1(s)}{s} & 0 \\ \frac{W_2(s)K(s)}{s} & 0 \end{bmatrix} \right\|_\infty \leq \gamma
\]

(14)
can be satisfied with $\gamma$ in $\mathbb{R}_+$ as small as possible. Let $A_{cl}$, $B_{cl}$, $C_{cl}$ and $D_{cl}$ be the state-space matrices corresponding to the one-input two-output system defined by the transfer function matrix $[W_1 S, W_2 KS]^T$. An LPV controller satisfying (14) can be synthesized and implemented as follows [13]

1. Find a matrix $X_{cl} > 0$, and controller matrices $A_{Ki}$, $B_{Ki}$, $C_{Ki}$, $D_{Ki}$ so that

\[
\begin{bmatrix}
    A_{cl}(\Theta_i)X_{cl} + X_{cl}A_{cl}(\Theta_i) & X_{cl}B_{cl}(\Theta_i) & C_{cl}^T(\Theta_i) \\
    B_{cl}^T(\Theta_i)X_{cl} & -\gamma I & D_{cl}^T(\Theta_i) \\
    C_{cl}(\Theta_i) & D_{cl}(\Theta_i) & -\gamma I
\end{bmatrix}
\]

is negative-definite for $i = 1, 2$, where $\Theta_1 = \theta^{-1}_{\min}$ and $\Theta_2 = \theta^{-1}_{\max}$.

2. For a given value of $\Theta = \theta^{-1}$, compute the matrices $A_K(\Theta)$, $B_K(\Theta)$, $C_K(\Theta)$ and $D_K(\Theta)$ defining the LPV controller as

\[
\begin{bmatrix}
    A_K(\Theta) & B_K(\Theta) \\
    C_K(\Theta) & D_K(\Theta)
\end{bmatrix} = \sum_{i=1}^{2} \alpha_i(\Theta) \begin{bmatrix}
    A_{Ki} & B_{Ki} \\
    C_{Ki} & D_{Ki}
\end{bmatrix}
\]

where $(\alpha_1, \alpha_2)$ is a convex decomposition of $\Theta$ such that $\Theta = \alpha_1 \Theta_1 + \alpha_2 \Theta_2$ and $\alpha_1 + \alpha_2 = 1$.

4 Simulation Results

The performance of the closed-loop system with the LPV controller is tested using MATLAB/Simulink and discrete event simulations.\(^2\) The number of TCP flows is taken to be $N = 150$, the link capacity $C = 500$ packets/sec, the desired queue size $q_0 = 150$ packets, and the buffer

---

\(^2\)The results from both were consistent so only those from the former are shown for better presentation and to save space.
size $q_{\text{max}} = 200$ packets. The RTT is assumed to take values between 0.3 secs and 0.7 secs. The controller design as outlined in Section 3 is carried out with the help of MATLAB Robust Control Toolbox.

Figure 2 shows the simulation results for 15 fixed values of RTT, linearly equally spaced between 0.3 and 0.7. Two other common control-theoretic approaches to AQM design are also implemented for comparison: a PID controller, and a switched $H_{\infty}$ controller. After subsequent trials, the best results that could be obtained with the PID controller were those based on a linearization around RTT $= 0.6$. The switched $H_{\infty}$ controller is based on two operating points RTT$_1$ and RTT$_2$, the best results for which were obtained when RTT$_1 = 0.4320$ and RTT$_2 = 0.6080$. The simulations illustrate that all controllers eventually succeed in achieving and maintaining the desired queue size of 150 packets. However, the LPV controller response is faster, with less overshoot and better damping over the entire parameter range.

The controllers were also tested for the case when RTT is time varying. The PID controller and the switched controller did not produce a stable closed-loop so these responses are not shown. The result for the LPV controller is shown in Figure 3. The top subfigure shows the variation in RTT versus time, which is a sinusoid with increasing frequency taking values between 0.3 and 0.7. The bottom subfigure shows the response of the closed-loop system. It can be observed that the LPV controller produces a stable closed-loop and is capable of maintaining the queue size very close to the desired value, even when RTT is time varying.

3Different cases for the variation of RTT were also tested with successful results, including square, triangle and sawtooth waveforms, as well as the case where RTT varies randomly according to various probability densities. However, only one case is shown in the paper to save space.
5 Conclusions

In this paper self-scheduled LPV control design was implemented for AQM. The controller design is based on a fluid flow approximation of TCP congestion control and utilizes RTT as the scheduling parameter. Simulations were carried out to evaluate the closed-loop system in its ability to keep the queue length at a desired level. Two other control-theoretic approaches to AQM, namely PID control and switching $H_\infty$ control, were also implemented for comparison. When RTT is constant, it was seen that the LPV controller outperforms the other two, producing a faster and better damped response with lesser overshoot over the entire parameter range. When RTT is time varying, the LPV controller is still capable of maintaining the desired queue size, whereas the PID and switching controllers do not produce a stable closed-loop.
